Absorption of Sodium γ -Hydroxybutyrate and Its Prodrug γ -Butyrolactone: Relationship between $In\ Vitro\ Transport\ and\ In\ Vivo\ Absorption$

C. ARENA and HO-LEUNG FUNG *

Received August 20, 1979, from the Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, N\ 14260. Accepted for publication October 11, 1979.

Abstract \square A qualitative relationship between *in vitro* transport and *in vivo* absorption of sodium γ -hydroxybutyrate and γ -butyrolactone was demonstrated. As with other short-chain acids, sodium γ -hydroxybutyrate showed capacity-limited transport *in vitro*, consistent with the previous observation that this drug exhibited slower *in vivo* absorption with increasing dose. The prodrug lactone, on the other hand, showed a higher intestinal flux than the acid in the everted gut, and *in vivo* absorption also was more rapid. Capacity-limited transport and absorption of the lactone appeared less evident. Thus, the increased oral hypnotic activity of the lactone over that of the acid most likely is a result of its more favorable intestinal transport characteristics.

Keyphrases \square Sodium γ -hydroxybutyrate—relationship between in vitro transport and in vivo absorption \square γ -Butyrolactone—prodrug for sodium γ -hydroxybutyrate, relationship between in vitro transport and in vivo absorption \square Hypnotic agents—sodium γ -hydroxybutyrate and γ -butyrolactone, relationship between in vitro transport and in vivo absorption

 γ -Hydroxybutyrate (I), a metabolite of γ -aminobutyric acid, is found endogenously in the human brain (1). When introduced intravenously, I is a useful anesthetic (2) and is beneficial in Parkinson's disease (3). However, oral administration of this compound results in decreased and variable pharmacological activity (4–6). Recently, oral doses of I totaling 50 mg/kg were shown to be useful in the treatment of narcolepsy and cataplexy in patients, but the duration of sleep induction after each oral dose lasted only for \sim 2 hr (7).

BACKGROUND

In previous animal studies in these laboratories (8–10), orally administered I was shown to be subject to first-pass metabolism at low doses (≤200 mg/kg) in rats. At higher doses (400–1600 mg/kg), systemic availability approached 100%, presumably due to saturation of first-pass metabolism, but the relative absorption rate appeared to decrease with increasing dose. Thus, although the extent of drug absorption was almost

complete, peak plasma I concentrations were relatively insensitive to increases in the oral dose and, in most animals, threshold hypnotic concentrations in plasma were not reached in spite of high oral doses.

The lactone analog of I, γ -butyrolactone (II), is hydrolyzed rapidly an exclusively in vivo to I (11, 12) and, therefore, can be classified as a prodrug. Compound II is rapidly and completely absorbed in vivo after or administration over a wide dose range. In contrast to I, the peak druconcentration after oral dosing of II was proportional to the dose, ar II was equally effective as a hypnotic whether given orally or intravenously (9).

The reason for the apparent difference in *in vivo* absorption chara teristics between I and II has not been delineated. In this paper, *in vit* experiments that compared the transport properties of these two corpounds across the everted rat gut are described.

EXPERIMENTAL

Reagents—Compound I, obtained as the sodium salt¹, and II¹ we used without purification. The buffer and assay reagents¹⁻³ were all r agent or analytical grade.

Everted Rat Gut Preparation—Male Sprague—Dawley rats, 260–3 g, were sacrificed by decapitation. An intestinal segment, ~12 cm lon was taken from a region 20 cm from the pylorus sphincter; it was evert and mounted according to the technique originally devised by Wilsand Wiseman (13) and modified by Crane and Wilson (14).

Flux Experiment—The everted gut was placed inside a test tube with mucosal side exposed to 90 ml of a 0.05 M physiological tromethamic buffer (pH 7.4) containing the appropriate drug concentration. All flustudies were carried out at 37°. At 5-min intervals up to 25 min, to serosal solution (~1 ml) was removed for the assay and replaced with equal volume of fresh buffer. Three or four replicate flux experiment were conducted at each initial mucosal concentration.

Spectrophotometric Analysis—The Hestrin (15) assay for sho chain O-acyl derivatives as adopted for I and II by Guidotti and Ballo (16) was employed. Conversion of I to II was effected by reaction w two parts of concentrated sulfuric acid² and subsequent neutralizati with 10 parts of 6 N NaOH².

RESULTS AND DISCUSSION

Transport of I and II through the everted rat gut was examined at various initial mucosal drug concentrations. Intestinal flux was determined for each animal preparation by linear regression of a plot of cumulative amount transported to the serosal side versus time. Representative plots showing intestinal transport of I and II at 0.40 M are given in Fig. 1. At low mucosal concentrations, linearity of flux was maintained throughout the experiment. However, at high I concentrations, positive deviations (increased flux) occurred at the later time points, suggesting possible tissue damage with prolonged drug exposure. In these instances, initial rates of transport restricted to the linear portion of the curve (usually 0–20 min) were used to calculate flux. In all experiments, the total amounts transported to the serosal side were small (<0.4% for I and <2.5% for II) compared to the total drug available from the mucosal pool. Thus, the initial mucosal concentration remained essentially unchanged throughout each experiment.

Figure 2 shows the relationships between intestinal flux of I and II and their respective mucosal concentrations. Over the concentration range studied, intestinal transport of II was considerably more rapid than that of I. At equimolar mucosal concentrations, the differences in flux between I and II were statistically significant at p < 0.001 using the Student t test. Compound II fluxes were ~ 5 , 7, and 10 times higher than I fluxes at 0.40, 0.79, and 1.19 M, respectively. In addition, I transport leveled off at concentrations above 0.40 M. If nonspecific effects on intestinal permeability could be ruled out, this flux behavior suggested the presence of a capacity-limited transport system for I in the rat intestine. In comparison, concentration-dependent transport of II was less evident.

In these experiments, the ionic strength in the mucosal solution was not constant over the concentration range studied. Although the mucosal solution was prepared with buffer, high I concentrations also could affect the pH slightly because I, as its sodium salt, is mildly basic. The leveling in I flux could, in principle, have been partially contributed to by non-specific ionic strength and/or pH effects created by increasing mucosal concentrations of the ionic drug. The possibility of this artifact was ruled out by the following experiment.

Flux studies were carried out at 0.08 M I under two sets of conditions. In one case, no pH or salt adjustments were made (Condition A: pH 7.4, $\mu = 0.23 \ M$); in the other case, sodium chloride and sodium hydroxide were added so that the pH and ionic conditions were equivalent to those present when flux was studied at 1.19 M I (Condition B: pH 8.1, $\mu = 1.34 \ M$). If ionic strength and pH affected flux significantly, then the observed fluxes under Conditions A and B would be different, with the flux of B similar to that observed at 1.19 M I. In fact, the flux of I was identical whether or not additional salt or alkalinizing agents were added.

In duplicate determinations, the fluxes obtained under Condition A were 2.2 and 2.3 μ M/min; those under Condition B both were 2.4 μ M/min. Thus, minor differences in pH and ionic strength contributed by changes

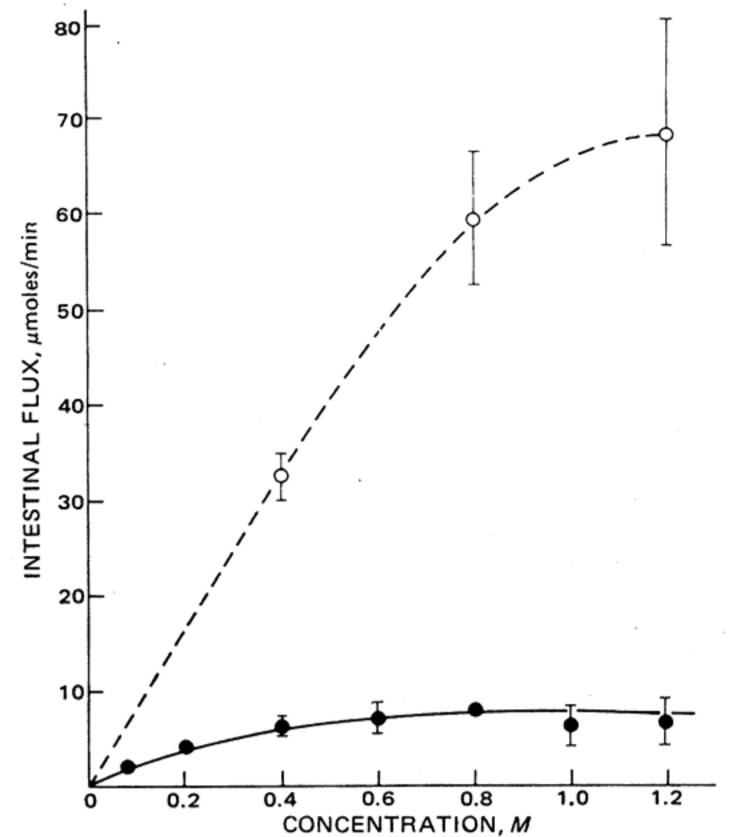

Figure 2—Concentration effect on the intestinal fluxes of I (\bullet) and II (\circ). Bars indicate standard deviations. When bars are absent, the standard deviations were too small to be shown.

in the mucosal I concentration did not affect flux significantly. Since II is nonionic, ionic strength and pH effects produced by increasing II concentrations were presumed to be negligible. Bender et al. (17) found the second-order alkaline hydrolytic constant of II to be ~0.2 liter/mole-sec at 25°. At pH 7.4, the hydrolysis half-life would be about 1000 days. Thus, conversion of II to I in the buffered mucosal solution was insignificant during the experiment.

The *in vitro* transport characteristics of I and II are consistent with their *in vivo* absorption properties reported previously (8–10). Compound I, which showed capacity-limited transport *in vitro*, also exhibited relatively slower *in vivo* absorption rates with increasing oral dose (10). Other short-chain acids, such as acetic and butyric acids, also have been shown to be transported *via* an active system (18, 19). Therefore, a capacity-limited absorption mechanism might be a reason for the decreased and variable activity of I when given in high oral doses to humans (4–7). The prodrug lactone II, on the other hand, showed a much higher intestinal flux than I in the everted gut and was almost instantaneously absorbed when orally administered (9). Capacity-limited transport of II, if existent, appeared to occur at much higher drug concentrations.

The present study demonstrated a qualitative relationship between in vitro transport and in vivo absorption of the two compounds studied. Thus, the increased oral activity of the lactone over that of its open-chain hydroxy acid is most likely a result of its more favorable intestinal transport characteristics. The usefulness of II has not been investigated in humans.
